Choosing the Best Shunt or Series Reference for Your Application

Voltage references are a key building block in data conversion systems. Understanding their specifications and how they contribute to error is necessary for selecting the right reference for the application. Figure 1 shows the application of a voltage reference in a simple analog-to-digital converter (ADC) and digital-to-analog converter (DAC). In each case, the reference voltage (V_ref) acts as a very precise analog ‘meter stick’ against which the incoming analog signal is compared (as in an ADC) or the outgoing analog signal is generated (as for a DAC).

As such, a stable system reference is required for accurate and repeatable data conversion; and as the number of bits increases, less reference error can be tolerated. Monolithic voltage references produce an output voltage which is substantially immune to variations in ambient temperature as well as loading, input supply, and time. While many ADCs and DACs incorporate an internal reference, beyond 8 to 10 bits it is rare to find one with sufficient precision as high-density CMOS technologies commonly used for data converters typically produce low-quality references. In most cases, the internal reference can be overdriven by an external one to improve performance. Terms such as “high precision” and “ultra-high precision” are common in reference datasheets but do little to help designers in their selection. This article seeks to provide an explanation of common reference specifications, rank their relative importance and show how a designer can use them in some simple calculations to narrow the search.
Figure 2 shows the two available voltage references topologies: series and shunt. A series reference provides load current through a series transistor located between \( V_{\text{IN}} \) and \( V_{\text{REF}} \) (Q1), and is basically a high-precision, low-current linear regulator. A shunt reference regulates \( V_{\text{REF}} \) by shunting excess current to ground via a parallel transistor (Q2). In general, series references require less power than shunt references because load current is provided as it is needed. The bias current of a shunt reference (IBIAS) is set by the value of RBIAS and must be greater than or equal to the maximum load current plus the reference’s minimum operating current (the minimum bias current required for regulation). In applications where the maximum load current is low (e.g. below 100 \( \mu \text{A} \) to 200 \( \mu \text{A} \)), the disparity in power consumption between series and shunt references shrinks. There is no inherent difference in accuracy between the two topologies and high- and low-precision examples are available in both varieties.

The advantages and disadvantages of the two architectures are summarized in Table 1. Generally, shunt references offer more flexibility (\( V_{\text{IN}} \) range, creation of negative or floating references) and better power supply rejection at the expense of higher power consumption while series references typically dissipate less power and can achieve better performance for extremely high-precision applications. The typical application diagram of data converters will often show a zener diode symbol representing the reference, indicating the use of a shunt reference. This is merely a convention, and in nearly all cases a series reference could be used as well.

Table 1. Series vs Shunt Architectures
As with all ICs, voltage references have standardized parameters for determining the right part for a design. The following are key specifications in order of importance that are pertinent to all suppliers.

1. Temperature Coefficient

The variation in $V_{REF}$ over temperature is defined by its temperature coefficient (TC, also referred to as “drift”) which has units of parts-per-million per degree Celsius (ppm/°C). It is convenient to represent the reference voltage temperature dependence as a polynomial for the sake of discussion:

$$V_{REF}(T) = V_{REF\;25°C} \left(1 + TC_1 \left(\frac{T}{25°C}\right) + TC_2 \left(\frac{T}{25°C}\right)^2 + TC_3 \left(\frac{T}{25°C}\right)^3 + \ldots\right)$$

$TC_1$ represents the first-order (linear) temperature dependence, $TC_2$ the second-order, and so on. Higher than first-order terms are usually lumped together and described as the “curvature” of the drift.

The majority of monolithic references are based on a bandgap reference. A bandgap reference is created when a specific Proportional To Absolute Temperature (PTAT) voltage is added to the Complementary To Absolute Temperature (CTAT) base-to-emitter voltage of a bipolar transistor yielding a voltage at roughly the bandgap energy of silicon (~1.2V) where $TC_1$ is nearly zero. Neither the PTAT nor CTAT voltage is perfectly linear leading to non-zero higher-order TC coefficients, with $TC_2$ usually being dominant. References designed for drifts less than 20 ppm/°C generally require special circuitry to reduce $TC_2$ (and possibly higher-order terms), and their datasheets will often mention some form of “curvature correction.” Another common type of reference is based on a buried-zener diode voltage plus a bipolar base-to-emitter voltage to produce a stable reference voltage on the order of 7V. The drift performance of buried-zener references is on par with that of bandgap references, although their noise performance is superior. Buried-zener references usually require large quiescent currents and must have an input supply greater than 7.2V, so they cannot be used in low-voltage applications ($V_{in} = 3.3V, 5V$, etc.).

**Figure 3. Different Methods for TC Calculation**

The temperature coefficient can be specified over several different temperature ranges, including the commercial temperature range (0 to 70°C), the industrial temperature range (-40 to 85°C), and the extended temperature range (-40 to 125°C). There are several methods of defining TC, with the “box” method being used most often. The box method calculates TC using the difference in the maximum and minimum $V_{REF}$ measurements over the entire temperature range whereas other methods use the values of $V_{REF}$ at the endpoints of the temperature range ($T_{MIN}, T_{MAX}$).
Neither method is ideal. The weakness of the endpoints method is the failure to account for any curvature in the drift (TC2, TC3, etc.). Calculating the incremental TC from room temperature to both the minimum and maximum temperatures improves the situation as information on TC2 can be garnered using three data points rather than two. While the box method is more accurate than using endpoints, it may underestimate TC if the temperature range of the application is smaller than the range over which the TC is specified.

2. Initial Accuracy

The initial accuracy of $V_{\text{REF}}$ indicates how close to the stated nominal voltage the reference voltage is guaranteed to be at room temperature under stated bias conditions. It is typically specified as a percentage and ranges from 0.01% to 1% (100-10,000 ppm). For example, a 2.5V reference with 0.1% initial accuracy should be between 2.4975V and 2.5025V when measured at room temperature. The importance of initial accuracy depends mainly on whether the data conversion system is calibrated. Buried-zener references have very loose initial accuracy (5-10%) and will require some form of calibration.

3. 0.1-10 Hz Peak-to-Peak Noise

The internally-generated noise of a voltage reference causes a dynamic error that degrades the signal-to-noise ratio (SNR) of a data converter, reducing the estimated number of bits of resolution (ENOB). Datasheets provide separate specifications for low- and high-frequency noise. Broadband noise is typically specified as an rms value in microvolts over the 10 Hz to 10 kHz bandwidth. Broadband noise is the less troublesome of the two as it can be reduced to some degree with a large $V_{\text{REF}}$ bypass capacitor. Broadband noise may or may not be important in a given application depending on the bandwidth of the signal the designer is interested in. Low-frequency $V_{\text{REF}}$ noise is specified over the 0.1 Hz to 10 Hz bandwidth as a peak-to-peak value (in $\mu$V or ppm). Filtering below 10 Hz is impractical, so the low-frequency noise contributes directly to the total reference error. Low-frequency noise is characterized using an active bandpass filter composed of a 1st-order high-pass filter at 0.1 Hz followed by an nth-order low-pass filter at 10 Hz. The order of the low-pass filter has a significant effect on measured peak-to-peak value. Using a 2nd-order low pass at 10 Hz will reduce the peak-to-peak value by 50 to 60% compared to a 1st-order filter.

Some manufacturers use up to 8th-order filters, so a designer should read the datasheet notes carefully when comparing references. From a design perspective, the 0.1 Hz to 10 Hz noise is mainly due to the flicker ($1/f$) noise of the devices and resistors in the bandgap cell, and therefore scales linearly with $V_{\text{REF}}$. For example, a 5V reference will have twice the peak-to-peak noise voltage as the 2.5V option of the same part. Reducing the noise requires considerably higher current and larger devices in the bandgap cell, so very
low noise references (<5 μVpp) often have large quiescent currents (hundreds of microamps to milliamps) and tend to be in larger packages. Buried zener references have the best noise performance available because no gain is required to generate the output voltage. Bandgap cells typically have a closed loop gain of 15 V/V to 20 V/V, causing device and resistor noise to be amplified.

4. Thermal Hysteresis
Thermal hysteresis is the shift in $V_{\text{REF}}$ due to one or more thermal cycles and is specified in parts-per-million. A thermal cycle is defined as an excursion from room temperature to a minimum and a maximum temperature and finally back to room temperature (for example, 25°C to -40°C to 125°C to 25°C). The temperature range (commercial, industrial, extended) and number of thermal cycles vary by manufacturer, making direct comparison difficult. More thermal cycles over a wider temperature range leads to a larger shift in $V_{\text{REF}}$. Even if the temperature range of the application is narrow, the heating of the part when soldering it to the PCB and any subsequent solder reflows will induce shifts in $V_{\text{REF}}$. The main cause of thermal hysteresis is a change in die stress and therefore is a function of the package, die-attach material and molding compound, as well as the layout of the IC itself. As a rule of thumb, references in larger packages tend to have lower hysteresis. Thermal hysteresis is not tested in production and datasheets only provide a typical shift.

5. Long-Term Stability
Long-term stability describes the typical shift in $V_{\text{REF}}$ after 1000 hours (6 weeks) of continuous operation under nominal conditions. It is meant to give the designer a rough idea of the stability of the reference voltage over the life of the application. The prevailing wisdom is that the majority of the shift in $V_{\text{REF}}$ occurs in the first 1000 hours as longterm stability is related logarithmically with time. A six-week test time is not feasible in production, so long-term stability is characterized on a small sample of parts (15 to 30 units) at room temperature and the typical shift is specified. Once a reference is soldered down on a PCB, changes in the board stress can also cause permanent shifts in $V_{\text{REF}}$. Board stress dependence is not currently captured in datasheets, so the designer should locate the reference on a portion of the PCB least prone to flexing. Different packages will have different sensitivity to stress; metal cans are largely immune, and surface-mount plastic packages become progressively more sensitive the smaller the package (for example, the same die will perform better in an SO-8 than an SC70 package).

6. Load Regulation
Load regulation is the measure of the variation in $V_{\text{REF}}$ as a function of load current and is specified either as a percentage or in parts-per-million per milliamp (ppm/mA). It is calculated by dividing the relative change in $V_{\text{REF}}$ at minimum and maximum load currents by the range of the load current. Load regulation depends on both the design of the reference and the parasitic resistance separating it from the load, so the reference
Voltage Reference Selection Basics

Voltage Reference Selection Basics June 2014

should be placed as close to the load as the PCB layout will allow. References with pins for both forcing and sensing \( V_{\text{REF}} \) provide some immunity to this problem. The impedance of the reference input is large enough (>10 kΩ) on many data converters that load regulation error may not be significant. Maximum load current information can be found in ADC/DAC datasheets specified as either a minimum reference pin resistance (\( R_{\text{REF}} \)) or a maximum reference current (\( I_{\text{REF}} \)). In situations where the reference is buffered with a high-speed op amp, load regulation error can usually be ignored. The dual of load regulation for shunt references is the ‘change in reverse breakdown voltage with current’ that specifies the change in \( V_{\text{REF}} \) as a function of the current shunted away from the load. It is calculated with the same equation as load regulation where load current is replaced with shunted current (\( I_{\text{SHUNT}} \)). The amount of shunted current depends on both the load current and the input voltage so the ‘change in reverse voltage with current’ specification also indicates line sensitivity.

7. Line Regulation

Line regulation applies only to series voltage references and is the measure of the change in the reference voltage as a function of the input voltage. The importance of line regulation depends on the tolerance of the input supply. In situations where the input voltage tolerance is within 10% or less, it may not contribute significantly to the total error. The extension of line regulation over frequency is the Power Supply Rejection Ratio (PSRR). PSRR is rarely specified but typical curves are usually provided in the datasheet. As with line regulation, the importance of PSRR depends on specifics of the input supply. If \( V_{\text{IN}} \) is noisy (generated with a switching regulator, sensitive to EMI, subject to large load transients), PSRR may be critical. The analogous specification for shunt references is the reverse dynamic impedance, which indicates the sensitivity of \( V_{\text{REF}} \) to an AC current. Noise on the supply powering a shunt reference is converted to a noise current through \( RBIAS \). Some shunt reference datasheets will specify the reverse dynamic impedance at 60 Hz and 120 Hz, and nearly all will provide a plot of reverse dynamic impedance versus frequency.

8. Special Features

In applications where power consumption is crucial, a series reference is usually the right choice. The quiescent current of most series references ranges from 25 μA to 200 μA, although several are available with \( IQ<1 \) μA. Low quiescent current generally comes at the expense of precision (TC and initial accuracy) and higher noise. Some series references can also be disabled via an external ENABLE / SHUTDOWN pin causing the quiescent current to drop to a few microamps or less when \( V_{\text{REF}} \) is not needed. A power-saving
mode is not possible in shunt references. Additionally, series references can have dropout voltages less than 200 mV, allowing them to be used at lower input voltages. Shunt references can also be used at low voltages, but the bias current may vary widely with changes in $V_{IN}$ due to the small RBIAS resistor required.

References do not require many external passive components but proper selection can improve performance. A bypass capacitor on $V_{REF}$ substantially improves PSRR (or reverse dynamic impedance in the case of a shunt reference) at higher frequencies. It will also improve the load transient response, and reduce high-frequency noise. Generally speaking, the best performance is achieved with the largest bypass capacitor allowed. The range of allowable bypass capacitors depends on the stability of the reference, which should be detailed along with ESR restrictions in the component selection section of the datasheet. When using a large bypass capacitor (>1 μF) it may be advantageous to bypass it with a smaller value, lower-ESR capacitor to reduce the effects of the ESR and ESL. The reverse dynamic impedance of a shunt reference varies inversely with the amount of current shunted. If noise immunity is more important than power consumption in a given application, a smaller RBIAS may be used to increase ISHUNT.

Some series references have a TRIM / NOISE REDUCTION (NR) pin to further enhance performance. By using a series of resistors shown in Figure 4, the TRIM/NR pin can be used to adjust output voltage by up to ±15 mV. The pin can also be used to create a low pass filter to decrease overall noise measured on $V_{OUT}$ by using a capacitor as shown in Figure 5. Note that increasing the capacitor size will continue to improve noise performance, but also increases startup time.

9. Other Considerations

Voltage references are becoming increasingly popular in the automotive space and as reliability becomes more critical, the need for AEC-Q100 qualified parts increases as well. The AEC-Q100 qualification was created by the Automotive Electronics Council and requires specific quality and testing procedures to ensure a device’s performance. On top of the general qualification, there are also grades from 0-4 which indicate the temperature range of the qualified device. At the time of this article, the most common is grade 1 where the operating temperature range of the device spans from -40 to 125°C. It should be noted that many manufacturers offer voltage references in the extended temperature range of -40 to 125°C and mention that the device is “suitable for automotive applications” but this does not mean that the device is AEC-Q100 grade 1-qualified. Therefore, designers for automotive applications should be cautious of devices that state
suitability for automotive applications unless it is specifically specified in the datasheet as AEC-Q100 qualified.

Due to the popularity of voltage references, many manufacturers have produced “identical” products and sometimes even release them as the same part number as the original manufacturer for part recognition. While the main performance characteristics are identical, there are times when there are subtle differences which could be of concern to a designer depending on their application. For example, the LM4040 offered from Texas Instruments has a wideband noise value of 35 µVRMS for a 2.5V output. The same part from another supplier has a wideband noise value of 350 µVRMS which is 10x the value even though the initial accuracy and temperature coefficient are the same. Other differences that are prevalently found are operating temperature range and current consumption. A designer should be careful when considering secondary or alternate parts with the same part number and should do a thorough comparison of the performance to ensure that the key parameters are indeed the same.

![Shunt References Diagram](image-url)
Voltage reference selection begins with satisfying the application operating conditions, specifically: nominal $V_{\text{REF}}$, $V_{\text{IN}}$ range, current drive, power consumption, and package size. Beyond that, a reference is chosen based on the accuracy requirements of a given data converter application. The most convenient unit for understanding how the reference error affects accuracy is in terms of the least significant bit (LSB) of the data converter. The LSB in units of parts-per-million is simply one million divided by two raised to the number of bits power.

Table 2 provides the LSB values for common resolutions.

ADCs / DACs have their own sources of error including integral nonlinearity (INL), differential nonlinearity (DNL), and gain and off-set error. If we consider the case of the more common unipolar data converter, voltage reference error is functionally equivalent to a gain error. INL and DNL gauge the nonlinearity of a data converter, on which the reference voltage has no effect. The gain and off-set errors can be understood conceptually.
by recognizing that ADCs / DACs have two reference voltages: $V_{\text{REF}}$ and GND in the case of a unipolar data converter, and $V_{\text{REF}}$ and $-V_{\text{REF}}$ for bipolar data converters. The offset error is the deviation in the output (in bits for an ADC and voltage for a DAC) from the ideal minus full-scale (MFS) value when a MFS input is applied. The MFS reference voltage is GND so $V_{\text{REF}}$ error has no effect. The gain error is the deviation from the ideal positive full-scale (PFS) output for a PFS input, minus the offset error. The PFS reference voltage is $V_{\text{REF}}$, so any shift in the reference voltage equates to a gain error. As such, the reference error can cause loss of dynamic range for input signals near PFS, which is also where it has the most pronounced effect on accuracy. The effect of reference error on a mid-scale (MS) input signal is half that for a PFS input, and is negligible for inputs near MFS. For example, a worst-case reference error of 8 LSB would result in a loss of 3 bits of accuracy for a PFS input, 2 bits of lost accuracy at mid-scale, and no loss of accuracy at MFS. If the designer has no idea what kind of reference error they can live with, matching the worst-case reference error to the maximum gain error is a reasonable starting point. In systems where error contributors are statistically independent, and consequently add together as a root mean squared sum, balancing the error contributions represents the optimal case. Otherwise, the error will tend to be dominated by one variable and the accuracy of the other variable(s) is essentially wasted.

In calculating the total error in $V_{\text{REF}}$, it is helpful to separate the specifications where a maximum value is guaranteed (TC, initial accuracy, load regulation, line regulation) and those where only a typical value is provided (0.1 Hz to 10 Hz noise, thermal hysteresis, and long-term stability). Other than initial accuracy, the guaranteed specifications are all linear coefficients and their contribution to the total error can be calculated based on the operating ranges of the reference (temperature range, load current, and input voltage).

\[
\begin{align*}
\text{ERROR}_{\text{TEMP}} &= TC \cdot (T_{\text{MAX}} - T_{\text{MIN}}) \\
\text{ERROR}_{\text{LOAD}} &= \text{LOAD\_REG} \cdot (I_{\text{LOAD\_MAX}} - I_{\text{LOAD\_MIN}}) \\
\text{ERROR}_{\text{LINE}} &= \text{LINE\_REG} \cdot (V_{\text{IN\_MAX}} - V_{\text{IN\_MIN}}) \\
\text{ERROR}_{\text{GUARANTEED}} &= \text{ERROR}_{\text{INITIAL\_AC\_CURACY}} + \text{ERROR}_{\text{TEMP}} + \text{ERROR}_{\text{LOAD}} + \text{ERROR}_{\text{LINE}}
\end{align*}
\]

Example using LM4132A 2.5V with 2.5V output

\[
\begin{align*}
\text{ERROR}_{\text{TEMP}} &= (10 \text{ ppm/°C}) \cdot (55^\circ \text{C} - 0^\circ \text{C}) = 550 \text{ ppm} \\
\text{ERROR}_{\text{LOAD}} &= (120 \text{ ppm/mA}) \cdot (0.5 \text{ mA} - 0 \text{ mA}) = 60 \text{ ppm} \\
\text{ERROR}_{\text{LINE}} &= (50 \text{ ppm/V}) \cdot (5.5 \text{ V} - 4.5 \text{ V}) = 50 \text{ ppm} \\
\text{ERROR}_{\text{GUARANTEED}} &= (0.05\% = 500 \text{ ppm}) + 550 \text{ ppm} + 60 \text{ ppm} + 50 \text{ ppm} = 1160 \text{ ppm}
\end{align*}
\]

In calibrated systems, initial accuracy can be dropped from the equation. The above calculation represents the worst case, and most of the time a reference will perform better than the guaranteed maximums (especially when it comes to line and load regulation where the maximum may be more a function of the testing system due to the very low signal-to-noise ratio of the measurement). It is worth noting that the statistical methods through which the guaranteed maximum specifications are calculated vary by manufacturer, so comparing datasheets may not tell the full story. If the designer wants to estimate the average reference
error, they can take the rms sum of the individual error sources rather than just adding them up. For simplicity, one can convert from peak to peak to rms value by using the equation peak-to-peak = 6.6 \times \text{rms}.

This is because 99.99% of the error will fall within 6.6 standard deviations of the total error distribution. In most cases, the TC error will be dominant, so TC error by itself gives a good indication of average reference performance. Datasheets only provide typical values for thermal hysteresis and long-term stability.

\[
\text{ERROR}_{\text{TOTAL}} = \text{ERROR}_{\text{GUARANTEED}} + \text{ERROR}_{\text{TC}} + \text{ERROR}_{\text{HYS}} + \text{ERROR}_{\text{TERMGGLE}} + \text{ERROR}_{\text{LF NOISE}}
\]

**Example using LM4132A 2.5V with 2.5V output**

\[
\begin{align*}
\text{ERROR}_{\text{TC}} &= 3 \times (75 \text{ ppm}) = 225 \text{ ppm} \\
\text{ERROR}_{\text{TERMGGLE}} &= 3 \times (50 \text{ ppm}) = 150 \text{ ppm} \\
\text{ERROR}_{\text{LF NOISE}} &= 10^6 \times \left(\frac{240 \mu\text{V}, \text{ppm}}{2.5\text{V}}\right) = 96 \text{ ppm} \\
\text{ERROR}_{\text{TOTAL}} &= 1160 \text{ ppm} + 225 \text{ ppm} + 150 \text{ ppm} + 96 \text{ ppm} = 1631 \text{ ppm}
\end{align*}
\]

but both are likely to vary a great deal unit to unit. The typical specification is not very helpful in estimating worst-case error without knowing the standard deviation of the distribution. Many times this information can be obtained by calling the manufacturer. Otherwise, a conservative, albeit crude, approach would be to multiply the typical specification by three or four to get a ballpark estimate of the worst-case shift. This is assuming that the standard deviation of the distribution is on the order of the mean value and designing for a two or three standard deviation worst case. The loss of resolution due to noise is harder to predict and can only really be known by testing a reference in the application.

Low-frequency noise should be very consistent on a unit-to-unit basis and no ‘sand-bagging’ of the typical value is required. Over a 10-second window, one can expect the $V_{\text{REF}}$ to shift by an amount equal to the $0.1 \text{ Hz to 10 Hz peak-to-peak specification}$.

Once the worst-case reference error in parts-per-million is estimated, it can be converted into LSB for different data converter resolutions using the values in Table 2. The worst-case accuracy loss at positive full-scale and mid-scale can then be calculated taking the log base-2 of the number of LSB of error.

\[
\begin{align*}
\text{ERROR}_{\text{TOTAL}}(\text{LSB}) &= \frac{1631 \text{ ppm}}{\text{LSB}} = 1.7 \text{ LSB (10 bit)} = 6.7 \text{ LSB (12 bit)} = 26.7 \text{ LSB (14 bit)} \\
\text{Worst Case Lost Accuracy} \quad (PFS) &= 0.8 \text{ bit (10 bit)} = 2.7 \text{ bits (12 bit)} = 4.7 \text{ bits (14 bit)} \\
\text{Worst Case Lost Accuracy} \quad (MS) &= 0 \text{ bit (10 bit)} = 1.7 \text{ bits (12 bit)} = 3.7 \text{ bits (14 bit)}
\end{align*}
\]
If the average rather than the worst case is considered, the rms sum of reference error contributors can be taken (replacing the maximums for the typicals).

**Example (LM4132A_2.5V):**

\[ \text{ERROR } I_{\text{rms}} = \sqrt{(550)^2 + (500)^2 + (50)^2 + (60)^2 + (75)^2 + (50)^2 + (96)^2} = 760 \text{ ppm} \]

\[ \text{ERROR } I_{\text{rms}} \text{ (LSB)} = \frac{760 \text{ ppm}}{760 \text{ ppm}} = 0.8 \text{ LSB (10 bit)} = 3.1 \text{ LSB (12 bit)} = 12.5 \text{ LSB (14 bit)} \]

**Typical Lost Accuracy**

- **PFS** = 0 bit (10 bit) = 1.6 bits (12 bit) = 3.6 bits (14 bit)
- **MS** = 0 bit (10 bit) = 0.6 bits (12 bit) = 2.6 bits (14 bit)

**Conclusion**

Using the voltage reference specifications to perform the above analysis, a designer should be able to predict the typical and worst-case accuracy loss due to reference error in their data conversion system. Repeating this exercise for several different references should provide the designer with more insight into what reference specifications are most critical in their application. These often include operating temperature range for temperature drift, initial accuracy if calibration is not possible, and low frequency noise which often cannot be filtered. Knowing which parameter is the dominant error factor helps to narrow down the reference options significantly and makes choosing the right reference easier.

3. Try the interactive selection tool to help instantly choose the proper reference for an ADC from the broad TI portfolio, see the WEBENCH® Series Voltage Reference Selector Tool at [ti.com/webenchvref](http://ti.com/webenchvref)

**About the author**

Mario Endo is a product marketing engineer for TI’s Power Products group where he is responsible for creating product awareness and identifying solutions for customer applications. Mario received his Master of Science from Santa Clara University.
IMPORTANT NOTICE

Texas Instruments Incorporated and its subsidiaries (TI) reserve the right to make corrections, enhancements, improvements and other changes to its semiconductor products and services per JESD46, latest issue, and to discontinue any product or service per JESD48, latest issue. Buyers should obtain the latest relevant information before placing orders and should verify that such information is current and complete. All semiconductor products (also referred to herein as “components”) are sold subject to TI’s terms and conditions of sale supplied at the time of order acknowledgment.

TI warrants performance of its components to the specifications applicable at the time of sale, in accordance with the warranty in TI’s terms and conditions of sale of semiconductor products. Testing and other quality control techniques are used to the extent TI deems necessary to support this warranty. Except where mandated by applicable law, testing of all parameters of each component is not necessarily performed.

TI assumes no liability for applications assistance or the design of Buyers’ products. Buyers are responsible for their products and applications using TI components. To minimize the risks associated with Buyers’ products and applications, Buyers should provide adequate design and operating safeguards.

TI does not warrant or represent that any license, either express or implied, is granted under any patent right, copyright, mask work right, or other intellectual property right relating to any combination, machine, or process in which TI components or services are used. Information published by TI regarding third-party products or services does not constitute a license to use such products or services or a warranty or endorsement thereof. Use of such information may require a license from a third party under the patents or other intellectual property of the third party, or a license from TI under the patents or other intellectual property of TI.

Reproduction of significant portions of TI information in TI data books or data sheets is permissible only if reproduction is without alteration and is accompanied by all associated warranties, conditions, limitations, and notices. TI is not responsible or liable for such altered documentation. Information of third parties may be subject to additional restrictions.

Resale of TI components or services with statements different from or beyond the parameters stated by TI for that component or service voids all express and any implied warranties for the associated TI component or service and is an unfair and deceptive business practice. TI is not responsible or liable for any such statements.

Buyer acknowledges and agrees that it is solely responsible for compliance with all legal, regulatory and safety-related requirements concerning its products, and any use of TI components in its applications, notwithstanding any applications-related information or support that may be provided by TI. Buyer represents and agrees that it has all the necessary expertise to create and implement safeguards which anticipate dangerous consequences of failures, monitor failures and their consequences, lessen the likelihood of failures that might cause harm and take appropriate remedial actions. Buyer will fully indemnify TI and its representatives against any damages arising out of the use of any TI components in safety-critical applications.

In some cases, TI components may be promoted specifically to facilitate safety-related applications. With such components, TI’s goal is to help enable customers to design and create their own end-product solutions that meet applicable functional safety standards and requirements. Nonetheless, such components are subject to these terms.

No TI components are authorized for use in FDA Class III (or similar life-critical medical equipment) unless authorized officers of the parties have executed a special agreement specifically governing such use.

Only those TI components which TI has specifically designated as military grade or “enhanced plastic” are designed and intended for use in military/aerospace applications or environments. Buyer acknowledges and agrees that any military or aerospace use of TI components which have not been so designated is solely at the Buyer’s risk, and that Buyer is solely responsible for compliance with all legal and regulatory requirements in connection with such use.

TI has specifically designated certain components as meeting ISO/TS16949 requirements, mainly for automotive use. In any case of use of non-designated products, TI will not be responsible for any failure to meet ISO/TS16949.
