1 Introduction

The premise of fractional N frequency synthesis is to use a feedback (N) divider that can assume fractional values, which allows lower N values and higher phase detector frequencies. This theoretically leads to improved phase noise because the N divider multiplies the phase noise of the PLL and lower spurs because the higher phase detector frequency implies spurs farther from the carrier that are easier to filter. In theory, this allows one to open the loop bandwidth, resulting in a design with better phase noise, lower spurs, and improved lock time.

Although all these benefits predicted by theory are true, they are based on the assumption that the fractional circuitry of the N counter is ideal. The actual performance improvements that are realized will not be as good as theory predicts because the circuitry involved in allowing the N counter to be fractional generates phase noise and spurs of its own. To really understand the true benefits of using a fractional N PLL and to use them to their greatest benefit, an understanding of the device, application, and architecture is required.

2 General PLL Concepts

2.1 Basic PLL Architecture

The phased locked loop (Figure 2-1) takes a fixed frequency, $f_{\text{OSC}}$, and divides it by a fixed value, R, to get the phase detector frequency, $f_{\text{PD}}$. This phase detector frequency is multiplied by N to get the final output frequency of $f_{\text{VCO}}$. The VCO frequency is tuned by changing the N counter value, and the channel spacing of this VCO is $f_{\text{CH}}$.

$$f_{\text{VCO}} = f_{\text{OSC}} \times \frac{N}{R}$$

For performance reasons, it is desirable to minimize the N counter value and maximize the phase detector frequency. Assuming the N counter value to be an integer, the largest that $f_{\text{PD}}$ can be chosen is the channel spacing, $f_{\text{CH}}$. However, there could be additional restrictions that can restrict $f_{\text{PD}}$ to a smaller divisor of $f_{\text{CH}}$. For instance, the phase detector frequency must also divide the oscillator frequency. This implies that:

$$f_{\text{PD}} = \text{GCD} (f_{\text{OSC}}, f_{\text{CH}})$$

In Equation 2, GCD(x,y) denotes the greatest common divisor, which is the greatest number that divides x and y. The AN-1865 Frequency Synthesis and Planning for PLL Architectures Application Report (SNAA061) discusses application of this concept to non-integer arguments as well as other frequency planning concepts. For instance, if a channel spacing of 1 MHz was desired, then it would be desirable to choose the phase detector frequency...
to be 1 MHz, but this would only work if \( f_{\text{osc}} \) was also a multiple of 1 MHz. If the oscillator frequency was 19.68 MHz, then the above formula would have to be used to calculate \( f_{\text{pd}} = \text{GCD}(19.68 \text{ MHz}, 1 \text{ MHz}) = 10 \text{ kHz} \).

2.2 Understanding Transfer Functions and Rolloff

In order to understand spurs and phase noise of a PLL, it is necessary to understand how they are shaped by the loop filter. The first step in doing so is to understand the open loop transfer function, \( G(s) \), which can be found from the phase detector gain, \( K_{\text{PD}} \), the VCO gain \( K_{\text{VCO}} \), and loop filter transfer function, \( Z(s) \).

\[
G(s) = \frac{K_{\text{PD}} \times K_{\text{VCO}}}{s} \times Z(s)
\]

From the open loop transfer function, the closed loop transfer function, \( CL(s) \), is given by:

\[
CL(s) = \frac{G(s)}{1 + G(s)/N}
\]

The closed loop transfer function is important because it shapes the phase noise and spurs. At frequencies less than the loop bandwidth, the closed loop transfer function is relatively flat as a function of frequency and has a magnitude of \( 20 \log(N) \):

\[
|CL(2\pi f)|_{\text{Loop Bandwidth}} = 20 \log(N)
\]

It is this factor in that multiplies the phase noise and integer \( N \) PLL spurs, which is the motivation for doing a fractional \( N \) PLL that allows lower \( N \) values. Although this factor holds true for integer \( N \) PLL spurs and phase noise, it does not always come into play for fractional \( N \) PLL phase noise and spurs. For this reason, it is more convenient to subtract off this factor of \( 20 \log(N) \) from magnitude of the closed loop transfer equation and define a new term called rolloff. Rolloff is a function of the offset frequency and shapes the phase noise and spurs:

\[
\text{rolloff}(f) = 20 \log |CL(2\pi f)|_{\text{Loop Bandwidth}} - 20 \log(N)
\]

Figure 2-2 shows the rolloff of a PLL system that has a loop bandwidth (BW) of 237 kHz, which will be used in later examples.

2.3 PLL Phase Noise

There are many contributors to the phase noise such as the reference oscillator, VCO, loop filter resistors, PLL dividers, PLL phase detector, and PLL charge pump. The oscillator, VCO, and loop filter resistor noise are application specific and not the focus of this application note. For the purposes of simplification, the noise of the
PLL dividers, phase detector, and charge pump will all be lumped together and referred to as PLL noise. There are basically three main contributors to the PLL phase noise. For all PLLs, there is a flat noise and 1/f (flicker) noise produced by the charge pump. In addition to this, fractional parts will also have noise added due to their fractional compensation. After all these noise sources are added together, they are shaped by the rolloff of the PLL system. The PLL phase can be calculated as:

$$\text{PLLnoise}(f) = 10 \times \log 10^{\text{PLLnoise_{flat}}(f)/10} + 10^{\text{PLLnoise_{1/f}}(f)/10} + 10^{\text{PLLnoise_{fractional}}(f)/10} + \text{rolloff}(f)$$  \hspace{1cm} (7)$$

For the purposes of modeling integer PLL phase noise, it is usually sufficient to only consider the impact of the PLL flat noise, provided that the phase detector frequency is not too high (<1 MHz). However, if the phase detector frequency is higher, the 1/f noise may become more exposed and need to be considered.

### 2.3.1 PLL Flat Noise

The PLL flat noise increases as the N divider value increases and the part-specific performance can be captured in a convenient index called the 1 Hz normalized phase noise, PN1Hz. If the charge pump current is increased, then this index will improve, but there will be a point of diminishing returns.

$$\text{PLLnoise_{flat}}(f) = \text{PN1Hz} + 20 \times \log N + 10 \log \frac{f}{1 \text{ Hz}}$$  \hspace{1cm} (8)$$

If the output frequency is held constant, but the N counter value is decreased, then this also means that the phase detector frequency increases. For this situation, the phase noise is proportional to $10 \cdot \log \left( \frac{N_{\text{New}}}{N_{\text{Old}}} \right)$. In other words, if the N counter value is decreased by a factor of 10 with the output frequency held constant, then the phase detector frequency will increase by a factor of 10 and the PLL flat noise will improve by 10 dB. However, this phase noise improvement may be masked at some offsets by the 1/f noise and the noise due to the fractional compensation.

### 2.3.2 PLL 1/f Noise

Active devices, including the PLL charge pump, produce a flicker (1/f) noise that decreases at 10 dB/decade with offset from the carrier. The 1/f noise of the PLL does not improve with higher phase detector frequencies as the flat noise does, so it becomes more important consideration when the phase detector frequency is high, as is the case with fractional PLLs. Simple experiments show that the PLL 1/f noise increases 20 dB/decade as a function of $f_{VCO}$, but is independent of $f_{PD}$ and the N counter value, provided that $f_{VCO}$ is held constant. This 1/f noise can be normalized to a 10 kHz offset and 1 GHz VCO frequency, PN10kHz. From this index, the unshaped 1/f noise of the PLL can be calculated anywhere.

$$\text{PLLnoise}_{1/f}(f) = \text{PN10 kHz} + 20 \times \log \frac{f_{VCO}}{1 \text{ GHz}} - 10 \times \log \frac{f}{10 \text{ kHz}}$$  \hspace{1cm} (9)$$

If the phase detector frequency is increased with a constant VCO frequency, the flat noise will improve, but the 1/f noise will not. Figure 2-3 shows phase noise data from an LMX2485 evaluation board driven with 100 MHz Wenzel crystal that has phase noise far below what is being measured. Raising the phase detector frequency improves the far out phase noise at offsets past 10 kHz, but for low offsets that are part of the 1/f noise, like 100 Hz, the impact is minimal.
Figure 2-3. 1/f Noise and Phase Detector Frequency (K_PD = 16X)

[1] establishes that the charge pump is the only phase noise source that is theoretically divided by the charge pump gain and therefore suggests the 1/f noise in Figure 2-3 is really due to the charge pump and not some other source.

Figure 2-4. Charge Pump Current and 1/f Noise (f_PD = 50 MHz)

3 Fractional N PLL Concepts

3.1 Fractional N Usage

Recall that for the integer N PLL, the phase detector frequency was limited to the channel spacing, or smaller. The reason for this is that the N counter is restricted to integers. For fractional PLLs, the N counter is allowed to assume some fractional values as well. The fractional denominator, Fden, for a specific device can either be fixed or programmable. Fnum is the fractional numerator and is intended to assume values from 0 to Fden-1. Traditional fractional N and delta-sigma fractional N PLLs are the same in this regard, although delta sigma PLLs typically have more flexibility for the choice of Fden due to architecture. The total N counter value is:

\[ N = N_{INT} + \frac{Fnum}{Fden} \]
For fractional parts, the phase detector frequency can now be chosen as:

\[ f_{PD} = \text{GCD}(f_{OSC}, f_{CH} \times F_{den}) \]  

(11)

Table 3-1 shows an example with a \( f_{CH} = 1 \text{ MHz} \) channel spacing and a \( f_{OSC} = 19.68 \text{ MHz} \) using three different kinds of PLLs.

</tbody>
</table>

For the delta sigma fractional part, \( f_{PD} \) can be chosen as high as \( f_{OSC} \). Although this device has a frequency doubler, the doubler cannot be used because this would violate the minimum N counter value of 31. For the avid reader, the AN-1865 Frequency Synthesis and Planning for PLL Architectures Application Report (SNA061) goes into more detail of how to calculate the GCD and calculate frequencies for fractional PLLs.

### 3.2 Simple Fractional N Architecture

Traditional fractional N PLLs allow \( f_{PD} \) to be increased by allowing the N counter to assume fractional values. The way that this is achieved is that the N counter is alternated between two integer values such that the average value is the desired fraction. Figure 3-1 shows a traditional fractional PLL with no analog compensation. Due to the digital nature of this circuit, it is common to represent this in the Z domain, which is discussed in more detail in Section 5. The integer portion of the N counter value, \( N_{INT} \), is handled normally and the fractional part is handled by additional fractional circuitry, which is made up of an accumulator and a quantizer. The previous output of the quantizer is subtracted from the input fraction and this error is added in the accumulator. When the error in the accumulator is less than one, the output of the quantizer is zero. However, when the error in the accumulator adds to one or more, then the output of the accumulator is one. On the next phase detector event, this output is subtracted from the fractional word input. In this way, the output of the quantizer is a stream of ones and zeros that have an average value equal to the desired fraction of \( \frac{F_{num}}{F_{den}} \).

![Figure 3-1. Traditional Fractional N PLL](image-url)
Consider the fractional PLL example in Table 3-1 with a desired output frequency of 902 MHz. In this case, the N counter value is $183 + \frac{41}{123}$, which simplifies to a fraction of $183\frac{1}{3}$. For the first two times the divider divides by 183, the frequency will be too high, but then for the third time when the divider divides by 184, this frequency will be lower in an amount such that the total period is equal to the period of the ideal signal.

Figure 3-2 shows that although the average frequency is correct, the actual frequency is frequency modulated between 183 and 184 MHz. This frequency modulation gives rise to undesired spurious tones in the frequency domain. In the time domain, this can be viewed as an instantaneous phase error. Because this error is presented to the phase detector, which is triggered only on the rising edges of the output of the N counter, only the errors in the timing of the rising edges matters. This error gives rise to large fractional spurs if not corrected. For the traditional fractional PLL, there are two common methods that are used to compensate for this instantaneous phase error. One method is to allow this error to go to the phase detector/charge pump and then cancel the resulting error current it produces with a current of opposite polarity. The challenge with this method is that it is difficult to get a current value that is good over voltage, process and temperature. A second method is to use an analog delay to make the output correspond to the ideal output. Although this method might be easier to optimize over voltage, process, and temperature, it also adds phase noise. Both the current compensation and the delay methods can certainly reduce the spurs, but they have their imperfections.

### 3.2.1 Delta Sigma Fractional PLLs

For the traditional fractional PLL, analog compensation is used to reduce the fractional spurs, although this has its shortcomings. Delta sigma PLLs aim to reduce spurs using digital techniques so that there is minimal added phase noise and the fractional spurs are reduced even lower. There are really two common digital techniques that are employed. The first technique involves varying the N counter value over a wider range of values in order to reduce the primary fractional spurs. Just as the first order modulator alternates the N counter between two values, the $n^{th}$ order delta sigma fractional PLL modulates the N counter between up to $2^n$ different values. A third order modulator could alternate between 8 different counter values and a fourth order modulator could alternate between 16 different counter values. As a rule of thumb, higher order modulators outperform lower order modulators, but not in all situations; this is application specific. Consider the modulator sequence for a generation of the fraction $1/4$.

</tbody>
</table>

A second technique used to improve sub-fractional spurs in delta sigma PLLs is called dithering. For the first order modulator example in Table 3-2, the cycle repeats every three time steps (each time step is 1/f_{PD}). The period is twice that for the second order modulator, 4 times that for the third order modulator, and 8 times that for the fourth order modulator. This periodicity is undesirable and can give rise to sub-fractional spurs, which are spurs that occur at a fraction of the primary fractional spur frequency. In order to reduce this periodicity, a technique called dithering can be used. Dithering involves randomizing this sequence so that it is pseudo-random and the period is not so obvious. By doing this, the sub-fractional spurs are reduced. In practice, dithering impacts sub-fractional spurs, but has little impact on the primary fractional spurs. In some situations, it can add small amounts of phase noise.

The traditional fractional PLL as shown in Figure 3-1 is technically a first order delta sigma PLL with analog compensation, although the industry standard for the term “delta-sigma” PLL typically assumes no analog compensation and the order is at least second order or at least dithering is used. There is more than one way to create a higher order delta sigma PLL, but one common way is the MASH (Multi-stAge noise SHaping) architecture. In this architecture, the output of each stage is fed into the next stage, and the errors from all stages are summed together. Figure 3-3 shows a third order delta sigma PLL using MASH architecture.

3.3 Fractional PLL Phase Noise
3.3.1 Simplified Delta Sigma Phase Noise

Figure 3-3 shows that the quantization noise from all stages except for the last is canceled out. If one makes the simplifying assumption that the quantizer output is a uniformly distributed random variable between zero and one, the spectral density of an n\textsuperscript{th} order delta sigma modulator can be calculated as follows [4]:
\[ |Y_{\text{Noise}}(0)|^2 = (2\pi)^2 \left( 2 \cdot \sin \left( \frac{\pi}{f_{\text{PD}}} \right) \right)^{2(n-1)} \cdot \left( \frac{1}{12 f_{\text{PD}}} \right) \]  

(12)

Figure 3-4. Simplified Delta Sigma Modulator Noise \((f_{\text{PD}} = 10 \text{ MHz})\)

Figure 3-4 shows this theoretical noise for a 10 MHz phase detector frequency. Notice at 5 MHz, which is exactly half of the phase detector frequency, there is a maximum value. In general, the quantization noise achieves its maximum value at \(f_{\text{PD}}/2\). After this frequency, the noise decreases and is also attenuated more by the loop filter. Therefore, it is this particular frequency that commonly is the one that is most likely to cause a problem. The theoretical value of this peak value in the noise is shown in Table 3-3.

</table>

It can also be shown that for offsets that are much less than \(f_{\text{PD}}/2\), the noise increases with a slope of \(20 \cdot (n-1)\) dB/decade. In other words, if the order of the modulator is increased, then a higher order loop filter may be necessary. One rule of thumb for delta sigma PLLs is that the order of the loop filter should be one greater than the order of the delta sigma modulator. This rule is approximate and over-conservative in some cases. In practice, if the loop bandwidth is narrow enough, then these higher order loop filters may not be necessary. It also turns out that although the fourth order modulator would theoretically require a fifth order loop filter, a fourth order loop filter is typically sufficient. Section 6 has more properties of the delta sigma modulator noise as well as their corresponding derivations.

3.3.2 Measured Delta Sigma Noise and Randomization Effects

To validate the modulator noise equation in Section 3.3.1, a LMX2485 PLL evaluation board was used with the wide loop bandwidth setup in Section 7 to have the rolloff as described in Figure 2-2. It must be firmly emphasized that many of these examples are done with much less filtering than is typically used to fully expose all the effects to be studied. In other words, it is invalid to compare these results to some other results without taking into account the impact of the loop filter. The measured delta sigma noise with the rolloff subtracted away is shown in Figure 3-5.
Comparing the measurements to the theoretical data, there is excellent agreement except at very low frequencies. At these low frequencies, the noise becomes flat. Further experiments showed that there was no consistent trend for this low offset noise for a particular modulator order, phase detector frequency, dithering mode, output frequency. In this case as shown in Figure 3-5, the quantization noise was well randomized and the assumption that it is a uniformly distributed random variable between zero and one holds. This is why there is such nice agreement.

Figure 3-6 shows the raw phase noise data taken with an E5052 phase noise analyzer with the spurs in dBC. Even though both fractions are both very close to 1/100, the one with the larger denominator shows that the noise is much more uniformly distributed with less discrete spurs, especially the one at 100 kHz offset.

When dithering was used, this also made the noise more randomized as shown in Figure 3-7.
Figure 3-8. Impact of Modulator Order (f_{PD} = 10 MHz, No Dithering, Fraction = 1/100)

Figure 3-8 shows the impact of the modulator order. Although higher order modulator does seem to produce less spurious content in this case, it is much more obvious in Figure 3-9 where the fraction of 1/100 is expressed in higher terms of 10000/1000000.

Figure 3-9. Impact of Modulator Order (f_{PD} = 10 MHz, No Dithering, Fraction = 1000/1000000)

These figures demonstrate that the delta-sigma modulator noise is best randomized when large fractions, higher order modulators, and dithering is used. Although these conditions are best for randomizing the delta sigma modulator noise, they might not be right for every application. In some situations, expressing fractions in larger terms might give rise to additional spurs at lower offsets. Higher order modulators help with randomization and also the primary fractional spur, but sometimes give rise to sub-fractional spurs that occur at a fraction of where the fractional spur would occur. Dithering randomizes the noise, but sometimes can degrade close-in phase noise. Also, if dithering is used with a fractional numerator of zero, it creates noise and spurs that would otherwise would not be there.
3.4 Fractional Spurs

In general, fractional spurs only exist when the fractional numerator is nonzero. They can be classified into three categories: integer boundary, primary, and sub-fractional. The integer boundary spur is a single spur that happens at an offset equal to the distance to the closest integer channel. The primary fractional spurs are those that happen at increments of the channel spacing, and sub-fractional spurs occur at sub-multiples of this. The following table gives an example of the offsets of these spurs for the case for a PLL operating at 2000.3 MHz with a phase detector of 20 MHz and a fraction of 3/200 with a 2\textsuperscript{nd} order modulator.

<table>
<thead>
<tr>
<th>Spur Type</th>

3.4.1 Integer Boundary Spurs

The integer boundary spur occurs at an offset equal to the distance to the closest integer channel and typically gets worse as the VCO frequency gets closer because it can not be filtered by the loop filter as well. There are two key mechanisms that cause this spurs that can be divided into in-band and crosstalk mechanisms.

3.4.1.1 In-Band Integer Boundary Spurs

The first step in understanding fractional spurs of any sort is to understand the behavior of a traditional fractional N PLL with no compensation for a worst case fraction. By doing a Fourier analysis on the quantizer output in Figure 3-2 the fractional spurs can be calculated as they are in [1]. Real world devices will have fractional compensation, and the effect of this will be to lower the fractional spurs by some fixed amount. The magnitude of these fractional spurs will change around, but the worst case is when \( F_{\text{num}}=1 \) and the offset frequency of this worst case spur will be \( f_{\text{PD}} / F_{\text{den}} \). For this worst case, a device-specific index of InBandSpur can be extrapolated from measured data as is done in Table 3-5, which is what this worst case fractional spur would theoretically be with no filtering from the loop filter.

To account for the effects of the loop filter, simply add the rolloff (refer to the rolloff equation in Section 2.2).

\[
\text{FractionalSpur (Worst Case)} = \text{InBandSpur} + \text{rolloff}(f_{\text{Spur}}) \quad (\text{Traditional Fractional Spur Equation})
\]

Figure 3-10 shows fractional spurs measured on the LMX2364 evaluation board with setup conditions described in Appendix C. Fnum fixed at one and Fden varied from 2 to 128 in steps of one. For this example, \( f_{PD} \) was 2 MHz, so therefore the spur offset frequency in MHz was \( 2 / F\text{den} \). There are some minor irregularities, such as near 62 kHz offset frequency and at higher offsets, but these can be explained by part-specific behaviors of the LMX2364 and approximations that break down down for Fden < 8. However, the general trend of both the compensated and uncompensated fractional spur following the rolloff of the loop filter is clear.

So far, only first fractional spur, which is at an offset of \( f_{PD} / F\text{den} \) has been discussed, but there are higher order fractional spurs. In general, the \( n^{th} \) fractional spur is at an offset equal to \( n \times f_{PD} / F\text{den} \). These spurs can also be predicted, but typically they are less troublesome than the first fractional spur because they are at higher offsets and are easier to filter. These spurs can also be predicted with excellent accuracy, as done in [1]. One easy case where these can be predicted is in the case when Fden is large (>20). In this case, the worst case for the \( n^{th} \) fractional spur occurs when Fnum = n and has a magnitude about the same as InBandSpur. For instance, if a part has InBandSpur of -18 dBc, \( f_{PD} = 2 \) MHz, Fden = 100, and Fnum = 7, then the spur at 140 kHz would be -18 dBc + rolloff(140 kHz).

The next question that might come up is how the first fractional spur might vary for a numerator that is not equal to one. One simple case is when Fnum = Fden -1, which yields the same spur spectrum as Fnum = 1. Following this case, the first thing one should check is that if Fnum and Fden have any common factors. If they do, then the first fractional spur will not be present. In the case that Fnum and Fden have a common factor, the easiest way to calculate the fractional spurs would be to simplify the fraction of Fnum / Fden to lowest terms and then to the analysis on this new fraction. For instance, if the fractional denominator was fixed to 123, the fraction is 3/123 would reduce to 1/41. So although most channels in this example would have fractional spurs at every multiple of 1.23 MHz \( 123 = 10 \) kHz, this particular frequency would have fractional spurs at every multiple of 1.23 MHz / 41 = 30 kHz. Another way of thinking about this would be that the first and second fractional spurs are not present for this channel, but the third fractional spur would be present. So provided that the fraction
simplifies to something with a numerator of 1 or Fden - 1, the fractional spurs can be predicted with the methods already discussed.

The next thing to account for is when the fraction simplifies to something that does not have a numerator of 1 or Fden - 1. To do this, a new term, SpurMagnitude, is introduced to quantify how close to the worst case the Fden is. A SpurMagnitude of one is the spur for the worst case numerator. A SpurMagnitude of 2 is for the second worst case numerator. Summarizing the results in [1], the following generalization can be made:

\[
\text{FractionalSpur} = \text{InBandSpur} + \text{rolloff}(f_{\text{Spur}}) - 20 \cdot \log(\text{SpurMagnitude})
\]  

(14)

Table 3-6. In-Band Uncompensated First Fractional Spur

<table>
<thead>
<tr>

<tr>
<td>kth Worst Case</td>
<td>int(Fdenk/3) and Fden - int(Fdenk/3)</td>
<td>-20 \cdot \log(\text{SpurMagnitude}) (If Present)</td>
</tr>
</tbody>
</table>

Summarizing further the results of [1], the second worst case for the spur occurs at when Fnum is int(Fden/2) or Fden - int(Fden/2). If it turns out that this value for Fden has common factors with Fden, then the second worse case is not present, and one just goes the third worst case. The third worst case occurs when Fnum is int(Fden/3) or Fden - int(Fden/3), provided that this value for Fnum has no common factors with Fden. The kth worst case occurs when Fden is int(Fden/k) or Fden - int(Fden/k), provided that this value for Fnum has no common factors with Fden. To further explain this, Table 3-6 applies this concept to the fractional PLL example given in Table 3-1 and assuming a theoretical uncompensated fractional PLL. In this case, Fden is 123 and the channel spacing is 10 kHz. Therefore, the first fractional spur will be 10 kHz offset from the carrier, and will have a worst case magnitude of 0 dBc occurring at a numerator value of 1 and 122. The second worst case for this fractional spur will be when the fractional numerator is int(123/2) or int(123/2 - 1) with a magnitude of -20·log(2). This works out to Fden = 61 or 62 with a magnitude of -6 dBc. Now for the third and fourth worst cases, these spurs are not present because int(123/3) = 41 and int(123/4) = 30 both have a common factor with 123. The pattern for the second and third worse cases for these higher order spurs is much more complicated than for the first order spur and beyond the scope of this application note. For more detailed information on these spurs, the avid reader is encourage to consult [1].

In some applications it can be possible to avoid some of these worst case spurs by changing the TCXO frequency or shifting the VCO frequency. For this example, consider what would happen if the crystal frequency was changed to 10 MHz. In this case, the phase detector frequency could be raised to 10 MHz, and the fractional spurs would be at offsets in multiples of 1 MHz from the carrier, instead of 10 kHz. This would be a massive improvement. However, further improvement is possible still. If the TCXO frequency was changed to 30 MHz, then, the fractional denominator, Fden, would be 30. Now the worst case fraction would be when the fractional numerator would be 1 or 29. However, these values correspond to frequencies of 901 MHz and 929 MHz, which are both out of the frequency band of 902 – 928 MHz, so these worst case numerators could be avoided. The second worst case would be when the fractional numerator is 15, but since this divides evenly into 30, the first fractional spur would not be present in this case either. The same thing would happen for the third fractional spur. So finally, on the fourth fractional spur, this spur would be present, but theoretically it would be 12 dB lower than what it would be for the 10 MHz TCXO.

In conclusion, the worst and most troublesome cases for traditional fractional spurs can be reasonably modeled provided that the fraction and rolloff are known. One observation regarding fractional spurs that, unlike integer PLL spurs, fractional spurs are theoretically independent of VCO frequency. This lays the foundation for the understanding for all fractional spurs, but for delta-sigma PLLs there are other complexities that need to be considered.
Figure 3-11. Measured Fractional Spurs (f_{PD} = 10 MHz, Strong Dithering, Fraction = x / 4194303)

Figure 3-11 shows delta sigma primary fractional spurs measured on the same modified LMX2485 evaluation board. It should be emphasized that although this figure and many others to follow might appear as a smooth graph, they are really a collection of discrete spur measurements taken with an automated test program over many different fractional numerators and should not be confused with phase noise plots.

Figure 3-12. Normalized Fractional Spurs (f_{PD} = 10 MHz, Strong Dithering, Fraction = x / 4194303)

Figure 3-12 shows the normalized fractional spurs, which are the measured fractional spurs with the rolloff subtracted away. One observation is that the normalized fractional spurs are relatively consistent until the spur offset gets close to f_{PD} / 2, which is the same offset where the phase noise peaks. Furthermore, at 1.67 MHz, which is f_{PD} / 6, the difference in normalized spur levels between modulator orders is about the same as it is in-band. Experiments with other loop bandwidths and phase detector rates show that this unshaped peaking at f_{PD}/2 is not really impacted much by the loop bandwidth, although it will always be at a frequency higher than the loop bandwidth because the PLL loop bandwidth can only be made as wide as about f_{PD} / 10. Although there is the shaping of the modulator at offsets far outside the loop bandwidth, these effects can easily be masked by spurs due to crosstalk, so it makes little sense to try to account for this. In other words, primary delta sigma fractional spurs can be roughly modeled in the same way as traditional fractional spurs. There may be various settings that can impact the value for InBandSpur, such as the modulator order, but once this is known for one offset, it can be estimated for any other offset as well. For offsets far outside the loop bandwidth, there are crosstalk effects that will be discussed later.

3.4.1.2 Impact of Dithering and Fractional Numerator on the Integer Boundary Spur

All the discussion so far has been done assuming a worst case fraction, which is a fractional numerator of 1 and Fden-1. For traditional fractional spurs, there was a big advantage if one could avoid the fractional numerator of 1 or Fden-1. For delta sigma PLLs, this benefit becomes more blurred and harder to predict, but is generally true provided that the fraction is well-randomized. In general, any large fraction (after being simplified to lowest terms) is well randomized. Also, for fractions that do simplify, such as 10000/100000, they still can be well randomized if higher order modulators (3rd or 4th) are used. Dithering is typically useful to make any fraction act more randomized, but if the fraction is small, it may also create extra phase noise and spurs at other offsets.
Figure 3-13 shows data taken from the LMX2485 PLL with a fractional denominator of 101. The phase detector frequency was 10 MHz and the spur at (10 MHz/101 = 99 kHz) was measured every time. The loop bandwidth was made very wide, so this is mostly inside the loop bandwidth. If dithering is not used, then basically every spur for every numerator looks like the worst cases of 1 and 100. However, if dithering is used, then there is a huge advantage if the worst case numerators of 1 and 100 can be avoided. Furthermore, by traditional PLL N theory, the next worse case would be for a fractional numerator of 50 and 51 which Table 3-6 would predict to be 6 dB lower. In this case they are closer to 20 dB lower! This experiment shows it can be very worthwhile to avoid these worst case spurs with delta sigma PLLs and dithering can be helpful.

Figure 3-14 shows the same experiment with a fractional denominator of 11. In this case, dithering helped all around with the spurs, since the fractional numerator was less randomized. However, now it is only about a 12 dB benefit of avoiding the worst case numerators of 1 and 10.

3.4.2 Out-Band Integer Boundary Spurs

For integer PLL spurs and traditional fractional PLL spurs, the models presented so far do a good job at predicting the spur levels. However, for primary delta sigma fractional spurs that are far outside the loop bandwidth, measured data quickly shows that there are other effects that need to be accounted for. Figure 3-15 shows primary fractional spurs measured an LMX2485 PLL. Far outside the loop bandwidth, the modulator order has minimal impact. If the rolloff is subtracted from the raw spur levels, then the normalized spur can be found as shown in Figure 3-16. Looking at this figure, you can see that the normalized spurs are nothing close to being a constant at frequencies outside the loop bandwidth and the fractional spur equation presented in Section 3.4.1.1 needs some adjustment.
Judging from the behavior of these primary delta sigma fractional spurs at high offsets, it seems that the unexplained effects are not being directly filtered by the loop filter. In fact, it seems that these unexplained effects follow the transfer function of the VCO rather than the PLL. The natural things to suspect would be noise on the VCO power supply or noise produced at the high frequency input pin getting back to the VCO output. Experiments were done on the LMX2485 evaluation board to investigate this and it was found that increasing the filtering to the VCO power supply had minimal impact, but there the spurs could be improved about 5 dB by decreasing the DC blocking capacitor or increasing the series resistor to the high frequency input pin. Because these spurs do not seem to be directly filtered by the loop filter, they will be referred to as crosstalk spurs (XtalkSpur). However, the nature of this crosstalk seems to be more something related to the isolation between the VCO output and the N counter input rather than crosstalk between board traces.

In Figure 3-15, observe that the spurs degrade at 20 dB/decade with the spur offset frequency. By treating the spur offset frequency as the modulation frequency and applying traditional FM modulation theory, these 20 dB/decade degradation of these spurs can be explained by:

\[ \text{Spur} = 20 \cdot \log(\beta), \quad \beta = \text{Frequency Deviation / Modulation Frequency} \]  

One factor that seems to have an impact on these crosstalk dominated spurs is the charge pump current. Figure 3-17 shows the impact of changing the charge pump current on this normalized spur for the LMX2485 PLL. Decreasing the charge pump current helps to a point, but after a certain threshold is reached, then it does not help any more.
In general, the following observations have been made regarding these crosstalk dominated spurs:

- Crosstalk effects are typically far outside the loop bandwidth.
- These spurs decrease 20 dB/decade, regardless of the number of poles in the filter.
- These spurs follow the shaping of the VCO transfer function.
- These spurs can be normalized to a 1 MHz offset frequency to create the index of BaseXtalkSpur.
- Although loop filter may have some residual impact, these spurs are not impacted nearly as much as the rolloff would predict.
- They increase as $10 \cdot \log(K_{PD})$ beyond a certain charge pump current.
- There may be some dependence, but there is no clear trend with $f_{VCO}$.

</tbody>
</table>

In general, the total fractional spurs for the LMX2485 and LMX2531 families of delta sigma PLLs can be decomposed as:

$$IBS_{SPUR} = 10 \cdot \log(10^{IBS_{InBand}/10} + 10^{IBS_{VCOXtalk}/10})$$

(16)

Figure 3-18 shows how the fractional spur levels shown in Figure 3-15 can be decomposed into a FractionalSpur and a XtalkSpur.
In Figure 3-18, observe the XtalkSpur at farther offsets decreases 20 dB/decade and tracks the VCO transfer function. The crosstalk spur can therefore be normalized to a 1 MHz offset frequency to create a part-specific index, BaseXtalkSpur, which relates to the crosstalk spur as:

\[
\text{XtalkSpur} = \text{BaseXtalkSpur} - 20 \cdot \log(\text{offset} / 1\text{MHz}) - 20 \cdot \log\left| \frac{1+G(2\pi j \cdot \text{offset})}{N} \right|
\]  

(17)

At offsets far outside the loop bandwidth, the transfer function for the VCO is one, but at frequencies below the loop bandwidth, it is less than one. Applying this theoretical model against the modeled data, Figure 3-19 shows that this model fits the measured data quite well.

The observations presented here are based on the LMX2485 and the LMX2531 evaluation boards, that may have some influence on the value of BaseXtalkSpur. If the spur level is high relative to crosstalk effects, then these crosstalk effects can be ignored. However, if their level is low, as is the case for delta-sigma fractional spur far outside the loop bandwidth, crosstalk effects need to be considered. Although these crosstalk effects could technically apply to all spurs, they are included in the discussion of delta sigma fractional N spurs because this is the only case where it really has a noticeable impact. Figure 3-10 shows spurs with a traditional fractional PLL that do not show these crosstalk effects, so this suggests that these crosstalk spurs may be something that are more inherent to delta sigma PLLs.

In conclusion, crosstalk effects are too significant to not be considered for delta sigma primary fractional spurs that are far outside the loop bandwidth. For integer PLL and traditional fractional PLL spurs, these crosstalk effects have not been observed. Perhaps the reason for this is that delta-sigma spurs are lower and therefore some of these crosstalk effects are more exposed. Another possible explanation is that the digital fractional circuitry in delta sigma PLLs could be producing noise that can crosstalk on the chip itself. If there is a question rather crosstalk effects are really dominating a spur, one simple test is to simply program the modulator order to a different value and see if the spur changes. If it does not, then this implies that crosstalk effects may be at play.
3.4.3 Delta Sigma Sub Fractional Spurs

For the first order modulator example in Table 3-1, the cycle repeats every three time steps (each time step is $1/f_{PD}$). The period is twice that for the second order modulator, 4 times that for the third order modulator, and 8 times that for the fourth order modulator. For this example, the second order modulator would theoretically have a fractional spur that is $\frac{1}{2}$ of the offset frequency (in addition to the primary fractional spur) because the period is twice as long. The third order modulator would theoretically have a sub-fractional spur that is $\frac{1}{4}$ of the primary fractional spur offset in addition to these other existing spurs. The fourth order modulator would have all these existing spurs and also a spur at $\frac{1}{8}$ of the offset of the primary fractional spur, although this sub-fractional spur is typically not present. These sub-fractional spur levels can change based on the fraction used, part architecture, dithering mode, and various bit settings in the part, which makes them a challenge to theoretically predict.

![Sub-Fractional Spurs (LMX2485E PLL, $f_{PD} = 2$ MHz, 2nd Order Modulator)](image)

**Figure 3-20.** Sub-Fractional Spurs (LMX2485E PLL, $f_{PD} = 2$ MHz, 2nd Order Modulator)

![Sub-Fractional Spurs (LMX2485E PLL, $f_{PD} = 2$ MHz, 2nd Order Modulator)](image)

**Figure 3-21.** Sub-Fractional Spurs (LMX2485E PLL, $f_{PD} = 2$ MHz, 2nd Order Modulator)

Figure 3-20 and Figure 3-21 show an LMX2485E PLL with a 200 kHz channel spacing at 50.2 MHz output frequency. Depending on how the part is set up, the sub-fractional spurs can vary. For case 1, the PLL was tuned to 50.2 MHz with a fractional word of 10000 / 50000 and dithering disabled. The result is a spectrum full of sub-fractional spurs that looks terrible. In case 2, the modulator was first reset, then set to 2nd order. Although the final settings for the part are exactly the same, the action of the modulator dramatically improved the spurs. In case 3, the PLL in case 2 was tuned to 50.1 MHz and then back to 50.2 MHz and the spurs again became very bad. What is going on is that the starting place in the delta sigma sequence is different. By using the reset modulator, this basically ensures a predictable spur performance, although it is a hassle. If dithering is used as in case 4, this issue of unpredictable spurs is resolved, but then the phase noise is greatly increased. For this example, the delta sigma noise and spurs are emphasized because the lower VCO frequency. This is because although other noise sources improve with lower VCO frequency, the delta sigma modulator noise and spurs are theoretically independent of $f_{VCO}$.

One confusing thing about sub-fractional spurs is that they can change based on the initial starting point of the modulator input. If they are measured at a particular frequency, then the VCO is tuned away and tuned back.
to the original frequency, they can change. Some parts have features such as dithering and an automatic reset of the modulator that can make these more predictable. This erratic behavior of sub-fractional spurs is emphasized in cases with wide loop bandwidths, low VCO frequencies, and low phase detector frequencies. In addition to this, the sub-fractional spurs tend to be more erratic for the second order modulator because it does not randomize enough in some cases. The third and fourth order modulators typically have less of an issue with this randomness. Dithering is very effective in making the sub-fractional spurs more predictable, but should be used with caution because it can increase the phase noise in certain situations. When dithering is used, it is often beneficial to express the fraction in higher terms.

In other words, even though 1/5 and 10000 / 50000 are mathematically equivalent, the larger fraction may yield better sub-fractional spurs. On the other hand, in this case, it can also create a bunch of sub-fractional spurs at multiples of f_{PD}/50000. If a fraction is not well randomized, then the phase noise lobes are typically broken up into smaller spurs. Inside the loop bandwidth, the fractional spurs are similar, but outside the loop bandwidth, the well randomized fraction typically can have better spurs than the randomized fraction.

![Figure 3-22. LMX2485E Fractional Spurs (Fden = 1/4)](image)

![Figure 3-23. LMX2485E Fractional Spurs (Fden = 1/5)](image)

For the LMX2485 family of delta sigma PLLs, expressing the fraction with an odd denominator can help as shown in Figure 3-22 and Figure 3-23. In this case, the phase detector frequency was shifted from 800 kHz to 1 MHz and this eliminated the sub-fractional spurs at the expense of making the primary fractional spurs a few dB higher. For the LMX2485 family of PLL, this relationship seems to hold for all odd denominators.

In conclusion, although sub-fractional spurs can be deterministic if the part is set up in a given way, there are many inherent nuances and it is very difficult to find one single rule that is best in all situations. It is difficult to know the optimal way to configure a part to reduce or eliminate these spurs without some experimentation.
3.5 Conclusion

Fractional N PLLs allow better resolution and performance by allowing the N counter to support fractional values. By supporting fractional values, the overall N counter can be made lower and the phase noise substantially reduced. Fractional spurs are created and there is a lot to say about how these fractional spurs are reduced. In the traditional PLL, this is corrected with analog compensation. Although analog compensation may be easier to understand and predict, the spurs are much higher than those with digital delta-sigma compensation. Fractional N PLLs provide the most benefits for applications that have low channel spacing and higher output frequencies, although they provide a significant benefit to almost every application. In fact, it is advantageous to use a fractional part at higher frequencies and then divide this down, since the spurs will be the same offset, but reduced in amplitude, and the fractional spurs are independent of VCO frequency.

5 Fundamental Z Transform Properties

The Z transform can be thought of as a discrete version of a Fourier transform that converts a time domain signal to the frequency domain. It has several applications, such as solving difference equations and finding the frequency content of discrete time-domain signals. In the context of delta-sigma PLLs, it is useful in order to find the frequency content of the output of the delta sigma modulator. In this context, the time step is the period of the phase detector frequency, $1 / f_{PD}$. The Z transform is defined as:

$$F(z) = \sum_{k=0}^{\infty} f(n) z^{-k}$$

(18)

There are a few properties of the Z transform that are useful to know as shown in Table 5-1.

<td>$\sum f(n)$</td>
<td>$1 / (1 - z^{-1})$</td>
<td>This is a summation which occurs in the accumulator of a fractional N PLL</td>
</tr>
</tbody>
</table>

The first property can be easily derived by multiplying both sides for the Z transform equation by a factor of $z^{-1}$. It is very useful to recognize this property that multiplying by a factor of $z^{-1}$ is the same as a one clock cycle delay. The second property is useful because this applies to any summation, which occurs in the accumulator of a PLL. A summation can be viewed as adding the previous sum to the current output as shown in Figure 5-1.

![Figure 5-1. Summation in the Z Domain](image)

There are situations where it is useful to know the spectral density of something with a digital output. For this, it is useful to develop a link between the discrete Z domain and the continuous frequency domain. Recall the Fourier transform:

$$F(\omega) = \int_{-\infty}^{\infty} f(t) e^{-j\omega t} dt$$

(19)

The following substitution can be made to convert from the Z domain to the frequency domain:

$$e^{j\omega} = e^{2\pi j (1 / f_{PD})} \Rightarrow Z$$

(20)
6 Derivation of Delta Sigma Noise Characteristics

From Figure 3-3, you can see that the output of an nth order modulator would be:

\[ Y(z) = \frac{F_{\text{num}}}{F_{\text{den}}} + (1 - z^{-1})^n \cdot Q_n(z) \]  

(21)

However, as discussed in good detail in [4] this result is incomplete because it does not account for the digital sampling action of the phase detector and the fact that the N counter value is not constant, but rather being dithered around. In order to account for these effects, it is necessary to introduce the term h(z):

\[ h(z) = 2\pi \cdot \frac{z^{-1}}{1 - z^{-1}} \cdot \frac{1}{f_{\text{PD}}} \]  

(22)

Accounting for this term, the modulator noise becomes:

\[ Y(z) = \frac{F_{\text{num}}}{F_{\text{den}}} + h(z) \cdot (1 - z^{-1})^n \cdot Q_n(z) \]  

(23)

To get the output spectrum of the delta sigma modulator, it is necessary to transform from the Z domain to the frequency domain, use the following substitution (Section 5):

\[ z = e^{sT} = e^{2\pi jT} = e^{2\pi jf / f_{\text{PD}}} \]  

(24)

As an intermediate step, the following derivation is useful:

\[
\frac{1 - z^{-1}}{1 - e^{-j\pi}} = \frac{1}{2} \cdot (\cos(x) - j \cdot \sin(x)) = (1 - \cos(x))^2 + \sin^2(x) \\
= 1 - 2 \cdot \cos(x) + \cos^2(x) + \sin^2(x) = 2 \cdot (1 - \cos(x)) \\
= 4 \cdot \sin^2(\frac{x}{2})
\]  

(25)

Applying the transform and identities yields [4]:

\[
|Y_{\text{Noise}}(f)| = \left( 2 \cdot \sin \left( \frac{xf_{\text{PD}}}{f_{\text{PD}}} \right) \right)^{2(n-1)} \cdot \frac{|Q_n(s)|}{f_{\text{PD}}}
\]  

(26)

The above formula applies to both phase noise and spurs. Q_n (z) is simply the output of the nth quantizer minus its input. Because the output of the quantizer can be zero or one, this is bounded between (and including) zero and one. The spectral density of the quantization noise, Q_n (s), can change based on the fractional word. However, if the fraction is large and the modulator order is 3 or 4, then it is a fair assumption to assume that this is a uniformly distributed random variable between zero and one [4]. Under this assumption, the spectral density of the quantizer output can be modeled as a uniformly distributed random variable between zero and one, which has a resulting spectral density of:

\[ Q_n(s) = 1/12 \]  

(27)

For noise, the appropriate function is [4]:

\[
|Y_{\text{Noise}}(f)|^2 = (2\pi)^2 \cdot \left( 2 \cdot \sin \left( \frac{xf_{\text{PD}}}{f_{\text{PD}}} \right) \right)^{2(n-1)} \cdot \frac{1}{12 \cdot f_{\text{PD}}}
\]  

(28)

In Figure 3-4, note there is a point at which all the modulators theoretically have the same performance. This can easily be found by setting:
\[2 \cdot \sin\left(\frac{\pi \cdot f}{f_{PD}}\right) = \pm 1\]  

(29)

This occurs at:

\[f = \frac{f_{PD}}{6} + k \cdot f_{PD}, \quad k = 0, 1, 2, \ldots\]  

(30)

Of most interest is the case where \(k=0\). Indeed there are theoretically higher order occurrences, but for these, other noise sources can mask this and the delta sigma noise tends to be better filtered out for these frequencies. The most interesting occurrence is therefore:

\[f = \frac{f_{PD}}{6}\]  

(31)

Another frequency of interest is where the unshaped noise peaks in value. This can be found by setting:

\[\sin\left(\frac{\pi \cdot f}{f_{PD}}\right) = \pm 1\]  

(32)

This has a solution of:

\[f = \frac{f_{PD}}{2} (2 \cdot k + 1), \quad k = 0, 1, 2, \ldots\]  

(33)

The magnitude of the first phase noise peak can be found by substituting this frequency:

\[
\text{PLLnoise}_{\text{fractional}}(f_{PD}/2) = 10 \cdot \log\left(2\pi \cdot \left(2 \cdot \sin\left(\frac{\pi}{2}\right)\right)^2 \cdot \frac{1\text{-Hz}}{12 \cdot f_{PD}}\right)
\]

\[
= 20 \cdot \log(2\pi) \cdot 10 + 20 \cdot \log(2) \cdot \left(\text{order-1}\right) - 10 \cdot \log\left(\frac{f_{PD}}{1\text{-Hz}}\right) \cdot 0.8
\]

\[
\approx 6 \cdot \text{order-1} - \log\left(\frac{f_{PD}}{1\text{-Hz}}\right) \cdot 0.8
\]  

(34)

One final property of the delta sigma modulator noise is the slope for lower frequencies at offsets much less than \(f_{PD}/2\). At these lower frequencies, \(\sin (x)\) can be approximated by \(x\) and the slope can therefore be approximated as:

\[
\frac{d}{df}\left[2\pi^2 \cdot \left(2 \cdot \sin\left(\frac{\pi \cdot f}{f_{PD}}\right)\right)^2 \cdot \frac{1\text{-Hz}}{12 \cdot f_{PD}}\right]
\]

\[
\approx k \cdot \left(\frac{f}{f_{PD}}\right)^{2(n - 1)}
\]

\[
\Rightarrow 20 \cdot (n - 1) \text{dB/decade}
\]  

(35)
7 Setup Conditions

This appendix discusses setup conditions that were used. Table 7-1 is a list of the equipment that was used. Automated test scripts were used for the spur measurements. To measure spurs at such low levels, the span of the spectrum analyzer was set to 10 Hz and the reported spur levels was the difference between the spur power and the carrier power. When phase noise was measured, special care was taken to ensure that the phase noise of the signal source was far below the noise being measured at the VCO output.

</tbody>
</table>

All these measurements were made with evaluation boards. For the case of the LMX2485 wide loop filter, the components on the board were modified to increase the loop bandwidth so that it would be easier to see the performance of the delta sigma modulator. In the other cases, the default loop filter that came with the board was used. One thing that was done on the LMX2364 and LMX2485 standard loop filters was that the phase detector frequency was decreased and the charge pump gain was raised in the same proportion. This preserves the same loop filter characteristics but makes it easier to measure the delta sigma noise and spurs.
